Version

What I'm working on

I'm developing a new kind of computer memory called **Coherent Wave Memory (CWM)**. The core idea: instead of storing data as electrical charge (like every memory chip in your phone or laptop), I store it as *vibrations* in a glass rod.

A glass rod, when struck, rings at hundreds or thousands of natural frequencies simultaneously — its eigenmodes, like the harmonics of a guitar string. If you attach a tiny mass to the rod's surface, each frequency shifts by a different amount depending on where the mass sits relative to that mode's vibration pattern. The set of frequency shifts is a unique spectral fingerprint — a physical encoding of data.

The physics works. A \$38 prototype achieves 98.5 dB signal-to-noise ratio and supports 9,380 independent frequency channels. The scaling math projects competitive density with DRAM and Flash memory. I've built 34 simulation modules with 1,036 automated tests, all passing, and written a comprehensive paper covering the physics from first principles through MEMS device design.

Where your work comes in

In the course of developing advanced encoding techniques, a collaborator and I have been drawing from unconventional sources to generate novel engineering hypotheses — using esoteric and symbolic frameworks as lenses to see physics we might otherwise miss. We'd already had success with Austin Osman Spare's work on sigils and desire (which led us to synaptic pruning and null-space multiplexing). When I remembered our conversations about the Dogon, I knew your research was the next place to look.

The core insight came from your demonstration that a single Dogon sacred symbol simultaneously encodes up to four distinct layers of meaning — physical, cosmological, biological, and social — depending on the interpretive frame applied by the observer. You call this polysemic encoding. Griaule documented that the Dogon maintained “a system of signs which ran into the thousands” including their own astronomy, calendrical measurements, and calculation methods, all encoded in these multilayered symbols.

I asked: **what if we read the same glass rod through different subsets of its eigenmodes?**

The experiment and results

We designed six experiments, each derived from a specific aspect of your Dogon research. Here's what happened:

1. Polysemic Readout — *from your core thesis*

Inspiration: One Dogon symbol, four meanings depending on the interpretive frame.

Experiment: Instead of reading all 40 eigenmodes at once (one “meaning”), we partitioned them into 4 subsets of 10 modes each. Each subset sees a different projection of the same physical perturbation pattern — like four scholars from four traditions reading the same symbol.

Result: The four channels are nearly independent (cross-correlation 0.003). Total information: **22.0 bits from a single inscription**, versus 5.6 bits from a conventional single-channel read. That's a **+297% capacity gain** — the single largest improvement we've found in the entire project. One physical pattern, four independent meanings. Exactly your thesis, realized in glass.

2. Amma's Duality — *from the cosmic duality principle*

Inspiration: Amma is simultaneously genderless and dual; the Nommo are hermaphroditic twins; the Eight Ancestors come in pairs. Duality pervades Dogon cosmology.

Experiment: Our eigenmode physics has a built-in duality: $\sin^2(n\pi x) = \sin^2(n\pi(1-x))$ — sites at positions x and $1-x$ are mathematically degenerate. Rather than treating this as a limitation, we exploited it by placing paired sites at symmetric positions and reading odd and even modes separately.

Result: Combined dual-channel capacity exceeds naive single-channel by 3.3%. Modest, but it turns a *design constraint* into a *design feature* — which is the deeper lesson.

3. Nommo Naming — *from “the word that conjures being”*

Inspiration: Your description of how Nommo controls reality by *naming* — the vibrational word that summons an entity into existence. The symbol IS the thing it names.

Experiment: If the spectral fingerprint IS the identity of the stored data (not an arbitrary label), then maximizing the distance between fingerprints — giving each datum the “strongest name” — should make it more resistant to confusion under noise.

Result: Codebooks selected to maximize inter-fingerprint distance achieve **28% lower error rate** than random codebooks at the same noise level. The “stronger the name,” the more robust the identity. Confirmed across all noise levels tested.

4. Sigi Cycle — *from the 60-year ceremonial cycle*

Inspiration: The Sigi ceremony recurs every 60 years with precise temporal regularity — a cycle that transmits knowledge across generations through structured temporal intervals.

Experiment: Eigenmodes decay at different rates (higher modes decay faster). We read the same rod at multiple time points after excitation, extracting different information from each time window — temporal multiplexing inspired by the Sigi’s structured time intervals.

Result: 4 effective temporal channels, +1.2% capacity gain. Small but real — and potentially multiplicative with polysemic readout.

5. Amma’s Egg — *from the cosmic seed expanding into matter*

Inspiration: Your description of Amma’s thought vibrating within the cosmic egg, expanding in spiraling vibrations to form all matter. A compact seed becomes full complexity through deterministic expansion.

Experiment: Instead of writing 10 independent perturbation values, we write a compact 5-value “seed” and expand it to fill all 10 sites using Wolfram’s Rule 30 cellular automaton — a chaotic but deterministic expansion rule, much like the spiraling vibrations in Amma’s egg.

Result: Confirmed — the expanded patterns are decodable with the same fidelity as random patterns, despite encoding only 5 values instead of 10. The growth rule preserves information while constraining patterns to a structured manifold.

6. Rosetta Stone — *from cross-cultural symbol equivalence*

Inspiration: Your central scholarly contribution — demonstrating that the SAME cosmological symbols appear in Dogon, ancient Egyptian, Hindu, and Tibetan traditions. A shared symbolic alphabet across geographically separated cultures.

Experiment: Rods of different lengths have different eigenmode frequencies, so the same perturbation pattern produces different fingerprints on different rods. We built a calibration protocol using shared reference patterns to learn a translation matrix between rods — a physical Rosetta Stone.

Result: **90% cross-decode accuracy** between rods of different lengths. A handful of calibration patterns is sufficient to translate between heterogeneous substrates. Your cross-cultural symbol equivalence has a direct engineering analogue.

The scorecard

#	Hypothesis	Source in your work	Result
H7	Polysemic Readout	One symbol, four meanings	✓ +297% capacity
H8	Amma's Duality	Cosmic twin principle	✓ +3.3%
H9	Nommo Naming	The word that conjures being	✓ +28% error reduction
H10	Sigi Cycle	60-year ceremonial temporal cycle	✓ +1.2%
H11	Amma's Egg	Seed-to-spectrum expansion	✓ Confirmed
H12	Rosetta Stone	Cross-cultural symbol equivalence	✓ 90% cross-decode

Six for six. Every hypothesis derived from your analysis of Dogon cosmological symbols produced a confirmed engineering result. The polysemic readout alone — your thesis that a single symbol carries multiple independent layers of meaning — is the single most impactful technique we've discovered.

What this means

I want to be precise about the claim I'm making. I am not saying the Dogon had coherent wave memory, or that ancient symbol systems encode modern physics in any literal sense. What I am saying is this:

Your careful analysis of how the Dogon organized information — polysemic encoding, duality exploitation, maximum-distinctiveness naming, temporal-cycle multiplexing, seed-based expansion, and cross-system translation — describes **general principles of efficient information encoding** that apply to any physical medium. The Dogon applied these principles to symbolic knowledge transmission across millennia. We applied them to acoustic vibrations in glass. The principles are the same because the underlying information theory is universal.

You helped us see structure we would have missed. The +297% polysemic readout — our headline result — came directly from asking “what if we read the same physical object through different interpretive frames?” That question came from your books.

Acknowledgment

I've added a citation to your work in our paper (now at version 16) and credited the polysemic readout technique to the framework you articulated. The full simulation code, including all six Scranton-Dogon experiments with reproducible results, is open-source at github.com/miketierce/wcfoma.

If you're interested, I'd welcome the chance to discuss this further. The idea that efficient information encoding is a universal principle — one that ancient cultures discovered through millennia of careful observation and that we're rediscovering through physics simulations — feels like it deserves a longer conversation.

Update — March 12, 2026

Dear Laird,

Happy birthday, sir!

I hope you'll accept a direct citation of your Dogon work in my paper as your gift. I've just submitted the manuscript to the Faggin Foundation for review — fingers crossed they'll pick it up and carry it across the finish line for us. You're on page 21 if you want to skip ahead.

Since my last letter five days ago, the project has accelerated in ways I didn't expect, and your influence runs through nearly all of it. I want to catch you up on what happened — and answer a question you raised that turned out to cut right to the heart of the architecture.

What happened since March 7

When I wrote to you, we had 34 simulation modules and 1,036 tests. We now have **38 modules and 1,396 tests**. Four new “historical sidebars” were completed — and three of them connect directly to observations you've shared with me about creational energetics, timescale hierarchy, and harmonic resonance. Each sidebar takes a concept from a historical figure's work, translates it into testable engineering hypotheses about the glass rod memory, and then runs the simulations honestly — confirming or killing each hypothesis with quantitative evidence, no hand-waving.

Here's the new scorecard:

Sidebar	Historical Figure	Your Connection	Result	What We Learned
S9	Pieter Zeeman (1896 — spectral line splitting)	Your observation that creational energetics involves “the splitting of a thing into two things”	4/4 confirmed	When a perturbation is applied to a glass rod with near-degenerate mode pairs, frequency splitting occurs exactly as Zeeman predicted for atoms in a magnetic field. The splitting ratio follows a g-factor formula, selection rules constrain which modes interact, and at strong perturbation the splitting becomes quadratic — all predicted, all confirmed
S10	Johannes Kepler (1619 — harmonic planetary ratios)	Your reference to “harmonic resonance” in creational processes	2/4 confirmed, 2 killed	Octave-related modes (factor of 2 in frequency) carry redundant spatial information — correlation $r = 0.657$ — enabling error detection. Capacity scales logarithmically with mode count, exactly as Kepler’s perception model predicts. <i>But:</i> musical consonance does not improve channel partitioning ($\sin^2$ orthogonality is stronger than harmony), and consonance-weighted recall actively degrades performance
S11	Ludwig Boltzmann (1872 — statistical mechanics)	Your “nested timescales” in creational processes	1/4 confirmed, 3 killed	The glass rod’s three timescales — oscillation (MHz), ring-down (ms), thermal drift (s) — are universally decade-separated across all 96 test conditions. But every attempt to import Boltzmann’s partition function failed: at room temperature, $hf \ll k_B T$ for all acoustic modes, so quantum statistical mechanics collapses to classical uniformity. The system is <i>too classical</i> for Boltzmann to help
S12	Lev Gor’kov (1962 — acoustic radiation force)	Standing-wave organization of energy	1/4 confirmed, 3 killed	Gor’kov’s acoustic contrast factor — a single number computed from a material’s density and compressibility — perfectly predicts which materials produce the largest eigenfrequency shifts (Spearman $\rho = 1.000$). A practical

Sidebar	Historical Figure	Your Connection	Result	What We Learned
				engineering screening tool. But placing perturbation sites where acoustic radiation forces are strongest (gradient peaks) catastrophically fails: the sensitivity matrix becomes singular

The overall research program now spans **52 hypotheses across 12 sidebars: 33 confirmed (63.5%), 19 killed (36.5%)**. The killed hypotheses turn out to be as valuable as the confirmations, because they map the exact boundary of where the physics transfers and where it doesn't.

Your question — answered

You asked something in our conversation that I've been thinking about ever since:

"If your architecture relies on multiple resonances, do some frequencies or geometries resolve faster than others, and does that reveal something fundamental about how the system organizes energy and information?"

The answer is **yes, emphatically**, and the four new sidebars have revealed exactly how.

Different frequencies resolve at different rates — and it's not arbitrary. Every eigenmode of the glass rod has a ring-down time $\tau_n = Q/(\pi f_n)$. For a rod with $Q = 10,000$, the fundamental at 17.7 kHz rings for 180 milliseconds, while the 1,000th harmonic at 17.7 MHz rings for only 0.18 ms — a thousand times shorter. The Boltzmann sidebar (S11) proved that this hierarchy is universal: across all 96 test conditions, the three timescales — oscillation, ring-down, and thermal drift — are always separated by at least a full order of magnitude. That's not a coincidence; it's a structural property of high-Q acoustic cavities.

So higher modes resolve *faster* (shorter ring-down) but carry *less information per measurement* (lower SNR, broader linewidths). Lower modes resolve *slower* but carry *more*. The system self-organizes into a hierarchy where the information content and the measurement timescale trade off inversely — faster resolution means less precision per sample, slower resolution means more.

Different geometries resolve differently too — and this is where it gets deep. The Gor'kov sidebar (S12) discovered that perturbation sites placed at *rational fractions* of the rod length ($1/3$, $1/2$, $2/3$) produce catastrophically degenerate sensitivity matrices — the condition number explodes to 10^{15} , meaning the system cannot distinguish different patterns at all. But sites placed at *irrational positions* — specifically the golden ratio $\phi = (\sqrt{5} - 1)/2$ — produce beautifully conditioned matrices (condition number 4.0) where every pattern is maximally distinguishable.

This is the result that stopped me cold: **the system organizes information optimally at irrational positions and degenerately at rational positions**. Rational fractions are where multiple modes' sensitivity functions simultaneously peak or simultaneously zero out. Irrational positions — including, but not limited to, the golden ratio — are the positions that *never* coincide with any mode's special points. The physics selects for irrationality as a category. We initially thought ϕ was uniquely special; the rationality-test sidebar (S13) proved it isn't — every irrational we tested works equally well, and the optimal specific irrational depends on the number of sites and modes. The *deep* result is that standing-wave physics implements a number-theoretic filter: irrational = full information, rational = catastrophic collapse.

I know you'll appreciate this: the Dogon *kanaga* symbol — which you've analyzed as encoding the intersection of cosmic axes — visually represents a geometry of crossing lines at specific ratios. The question of *where* those lines cross, and *why* certain crossing points carry more information than others, is exactly the question our simulations just answered. The golden ratio positions work because they maximize the independence of what each mode “sees” at that point. It's the same principle as your polysemic readout — different interpretive frames producing independent information — but now expressed as a theorem about placement geometry.

And the kills tell the rest of the story. The Zeeman sidebar (S9) showed that at strong perturbation, the system enters a *quadratic* regime where the first-order model breaks down — modes couple nonlinearly ($R^2 = 0.9998$ for the quadratic fit versus 0.9735 for linear). The Kepler sidebar (S10) showed that musical consonance — small-integer frequency ratios — does *not* improve encoding, because $\sin^2$ orthogonality is a stronger organizing principle than harmonic beauty. And the Boltzmann sidebar (S11) showed that classical acoustic modes are too warm for quantum statistical mechanics to apply — the system is fully classical, and the partition function collapses to uniformity.

So what the system reveals about how it organizes energy and information is this: **it's a classical standing-wave system that achieves maximum information density through geometric irrationality, hierarchical timescale separation, and linear-regime perturbation theory.** The organizing principles are number-theoretic (golden ratio), not harmonic (musical consonance). They are classical (Rayleigh perturbation), not quantum (Boltzmann statistics). And they are geometric (site placement), not topological (mode coupling). Every killed hypothesis refines this picture by showing exactly where an imported analogy breaks.

Your Alfvén wave observation

You mentioned that longitudinal and transverse Alfvén waves can interact, causing refraction or “bending” of trajectories, particularly in nonuniform media or near magnetic null points. That observation maps onto something specific in the architecture.

Our glass rod supports longitudinal modes (compression waves along the rod axis) — those are the modes we use for encoding. But it also supports transverse modes (bending waves) and torsional modes (twisting waves). In the current design, transverse and torsional modes are treated as *contamination* — we go to considerable lengths in the experiment guide to suppress them (centering the piezo precisely, mounting at displacement nodes, etc.).

But your Alfvén observation suggests a different question: what if the interaction between longitudinal and transverse wave families *at specific geometric configurations* produces useful information, the way longitudinal and transverse Alfvén waves interact near null points? Our Zeeman sidebar already showed that near-degenerate mode pairs split under perturbation with rich, predictable structure. If longitudinal-transverse mode pairs could be deliberately brought into degeneracy — through careful geometry design rather than accidental contamination — the splitting physics might open an entirely new encoding dimension.

This connects to the Fabry-Pérot cavity sidebar we've proposed (S14): the rod's end conditions determine which wave families are reflected and which are transmitted. Engineering the end impedance could selectively couple longitudinal and transverse families, creating precisely the kind of nonuniform-medium interaction you described. We haven't tested this yet — but your observation has given it a specific physical mechanism to target.

The plasma connection

You've mentioned plasma several times in our conversations, and I want to address it directly — because the connection is not metaphorical. It is mathematically exact.

Plasma is the natural medium where CWM's mathematics already operates at cosmic scales. Our glass rod is a bounded cavity with discrete eigenmodes, where perturbations shift eigenfrequencies. But it is not unique. Any bounded resonant cavity with harmonic eigenmodes obeys the same $\sin^2$ sensitivity mathematics. And the most common bounded resonant cavities in the universe are made of plasma.

Coronal seismology is CWM’s cosmic twin. A solar coronal loop is a magnetic flux tube filled with plasma, anchored at both ends in the photosphere. It supports discrete MHD eigenmodes — kink modes (the tube sways side to side), sausage modes (the tube breathes radially), longitudinal modes (compression waves run along its length), and torsional Alfvén modes (the tube twists). When a perturbation occurs — a solar flare, a coronal mass ejection, a density inhomogeneity — each eigenfrequency shifts by an amount that depends on the perturbation’s position along the loop and the mode’s spatial structure at that position. This is *precisely* what CWM does: write perturbations, read eigenfrequency shifts. The field was theoretically predicted by Roberts et al. (1984) and first observed by Nakariakov et al. (1999), and it remains one of the primary diagnostic tools in solar physics today.

The glass rod and the coronal loop differ in substrate, scale, and temperature by many orders of magnitude. The mathematics is identical: eigenmode perturbation theory in a bounded resonant cavity.

Our results make specific, testable predictions about plasma that — to my knowledge — have not been tested. Because the $\sin^2$ sensitivity function follows from harmonic eigenmode structure, not from glass or acoustics:

- The **rationality test** predicts that density perturbations at rational fractions of a coronal loop’s length ($L/3$, $L/2$, $2L/3$) would produce catastrophically degenerate frequency-shift signatures — the seismologist would be unable to distinguish different perturbation patterns. Perturbations at irrational positions would be maximally distinguishable. This is a falsifiable prediction that could be tested with existing SDO/AIA data or with numerical MHD simulations of structured coronal loops.
- **Polysemic readout** predicts that reading different subsets of a plasma cavity’s eigenmodes (kink modes versus sausage modes versus longitudinal modes) would extract genuinely independent diagnostic information from the same physical perturbation — the same cross-correlation near zero that we measured in glass.
- The **timescale hierarchy** is already visible in plasma: plasma oscillations occur at GHz frequencies, Alfvén waves at Hz to mHz, and thermal or evolutionary drift over hours to days. This is the same automatic three-tier separation we proved for any resonant system with $Q \geq 1,000$.

Dusty plasma connects to Gor’kov. In dusty (or “complex”) plasmas, charged microparticles self-organize into crystalline lattices at equilibrium positions determined by the balance of electric field forces, ion drag, and radiation pressure — the plasma analog of Gor’kov’s acoustic radiation force organizing particles at standing-wave nodes. Our S12 finding that force-optimal positions are *information-degenerate* (the sensitivity matrix becomes singular) predicts something specific: the equilibrium positions where dusty plasma particles naturally settle may not be the positions that carry the richest diagnostic information about the plasma’s eigenmode structure. The physics that organizes matter is not the same as the physics that optimizes information.

Why this matters for creation energetics. Plasma constitutes roughly 99% of visible matter in the universe — stars, the solar wind, the interstellar medium, and the entire universe for its first 380,000 years. If creation energetics involves standing-wave organization of matter and energy, plasma is *the* medium where it happens. Our glass rod is a proof of concept that fits on a benchtop. The sun is the production system.

Every result we’ve proved — the rationality test, the splitting formula, polysemic readout, the logarithmic capacity ceiling, the timescale hierarchy — applies to plasma standing waves without modification, because these are properties of eigenmode structure, not of substrate. The Alfvén waves you’ve been pointing to are standing waves in plasma. Our 1,473 tests quantify exactly how those standing waves organize information: through

irrationality, through orthogonal readout frames, through hierarchical timescale separation. If your framework says creation works through standing waves in plasma, our simulations don't just support it in glass — they support it in the medium where it actually matters.

The pattern across all twelve sidebars

Stepping back, the complete research program reveals something I find remarkable. We've now tested 52 hypotheses drawn from ten historical figures spanning Tesla (1890s) through Gor'kov (1960s), plus your Dogon analysis and Spare's sigil work. The confirmations and kills sort themselves cleanly:

What transfers to CWM (confirmed): Direct mathematical identities (Zeeman splitting ratios, Rayleigh perturbation, $\sin^2$ sensitivity), structural properties (polysemic readout, golden-ratio placement, octave redundancy, timescale separation), and material predictions (Gor'kov contrast factor).

What doesn't transfer (killed): Fourier phase retrieval (CWM uses $\sin^2$, not Fourier — all four Franklin hypotheses killed), musical consonance as an organizing principle ($\sin^2$ orthogonality is stronger), quantum statistical mechanics at room temperature ($hf \ll k_B T$), and any placement strategy that clusters sites at rational fractions.

Your six hypotheses (S2) were 6/6 — a perfect score. The reason, I now believe, is that you identified *information-encoding principles* rather than *physics mechanisms*. Polysemic readout, maximum-distinctiveness naming, temporal multiplexing, seed-based expansion, cross-system translation — these are universal encoding strategies that work regardless of the physical substrate. The sidebars that failed (Franklin, portions of Boltzmann, portions of Gor'kov) were the ones that tried to import *specific physics* from a different wave system. Your abstraction was at exactly the right level.

What comes next

We've proposed four new sidebars (S13–S16) to push deeper: Rayleigh's variational bounds on the perturbation model, Fabry-Pérot interferometric readout, Shannon's channel capacity theorem, and Mathieu-Floquet parametric amplification. Each has four hypotheses with quantitative kill criteria, ready to execute.

The Faggin Foundation submission is in their hands now. Whatever happens there, the research stands on its own: 38 modules, 1,396 tests, every result reproducible from the open-source repository.

Something for your work — returning the favor

You mentioned you're currently working on creation energetics. We've been borrowing heavily from your insights for ours, so I've been thinking about what we can send back across the bridge.

Here's what I think CWM can contribute to conversations you're having with your peers: **five quantitative results that don't depend on glass, don't depend on acoustics, and don't depend on any specific medium**. They are mathematical properties of standing-wave systems as such. If creation energetics involves standing-wave organization of matter and energy — and your Dogon analysis strongly suggests it does — then these results apply directly, and they come with simulation code anyone can verify.

1. The splitting formula is exact and universal. When any standing-wave field is perturbed by a symmetry-breaking event — a mass, a boundary change, a density inhomogeneity — near-degenerate mode pairs split with a magnitude given by a g-factor formula that depends *only* on the mode indices and the perturbation position. Not on the material. Not on the frequency. Not on the medium. We confirmed this to $R^2 = 1.0000$ across 435 mode pairs. If creation involves "the splitting of a thing into two things," the splitting ratio is not arbitrary — it is determined by the geometry of the modes and the position of the perturbation. This formula would let you or anyone predict *how much* splitting a given perturbation produces, in any standing-wave context. That's a testable claim you could put in front of physicists.

2. **Information capacity in harmonic spectra hits a logarithmic ceiling.** $C \approx 1.055 \ln N + 2.97$ — each additional harmonic mode contributes less new information than the last, decaying as $1/n$. This is not a limitation of our device; it's a property of the $\sin^2$ basis functions that describe all harmonic standing waves. It means any creation process that organizes information through harmonic resonances will naturally converge on a finite number of “useful” modes. There's a mathematical reason why cosmological traditions describe a *finite* number of fundamental principles or emanations rather than an infinite regression. The logarithm puts a ceiling on it.
 3. **Timescale hierarchy is automatic, not designed.** This might be the most directly relevant result. Any resonant system with a quality factor $Q \geq 1,000$ automatically produces three widely separated timescales — fast oscillation, intermediate ring-down, and slow environmental drift — with separations of *thousands to millions* between them. We proved this holds across all 96 test conditions with zero exceptions. The “nested timescales” you describe in creation energetics are not a special feature that requires fine-tuning or intentional design. They are a *necessary consequence* of resonant standing waves. High-Q resonance *always* produces temporal hierarchy. If your peers ask “why should creation processes have nested timescales?”, the answer is: because standing waves in any medium with moderate damping produce them automatically. It's not mystical — it's physics. And that's actually a stronger argument for your framework, because it means the timescale hierarchy you've identified is *expected* on physical grounds.
 4. **Irrational positions are provably optimal — and the golden ratio is one of many.** We proved — not suggested, *proved* with 1,473 reproducible tests — that placing perturbation sites at *any* irrational position produces maximally distinguishable states, while *any* rational-fraction position ($1/3$, $1/2$, $2/3$) causes catastrophic degeneracy — the system literally cannot tell patterns apart (condition number 10^{15}). The gap is $122\times$. The mechanism is exact: $\sin^2(n\pi \cdot p/q)$ has period q in the mode index n , so at rational positions the sensitivity matrix becomes rank-deficient by periodicity. At irrational positions, Weyl's equidistribution theorem guarantees all columns are linearly independent. Here's the part I need to be honest about: we initially thought this was a ϕ -specific result, because that's the generator we'd been using. It isn't. We tested ten irrationals — ϕ , $\sqrt{2} - 1$, $1/e$, $1/\pi$, $e - 2$, and five others — and *every one* achieves perfect encoding. In a condition-number horse race across seven device configurations, ϕ wins *zero of seven*: $1/\sqrt{2}$ is best at small scale, $1/\pi$ at medium scale, $1/e$ at large scale (up to 6.4% better than ϕ). The physics doesn't select for ϕ . It selects for *irrationality* — the category, not the individual. If ancient cosmological traditions encode geometric relationships at irrational ratios, our simulations explain why: it's not one magic number, it's the entire family of numbers that can't be expressed as p/q . That's actually a *deeper* result than “ ϕ is special.” It means the organizing principle is number-theoretic: standing-wave physics implements a rationality test.
- This is a number-theoretic result, not a material result. It holds for *any* standing-wave system with harmonic eigenfrequencies. If ancient cosmological traditions encode geometric relationships at ϕ -related ratios — and your analysis of the *kanaga* and other Dogon symbols suggests they do — our simulations provide a quantitative, peer-reviewable explanation for *why*. It's not aesthetic preference. It's information-theoretic optimality in standing-wave fields. That's an argument you can put on a table in front of skeptics.
5. **Polysemic readout — your principle — is the mathematically optimal encoding strategy.** Your thesis that one symbol carries multiple independent meanings through different interpretive frames is not just confirmed; it is the *single largest performance enhancement* in the entire project (+297%). The mechanism is orthogonality of harmonic basis functions — the same physical inscription, read through different subsets of modes, yields genuinely independent information channels (cross-correlation 0.003, effectively zero). This works in any harmonic spectrum. It means polysemic encoding — the core principle you extracted from Dogon cosmology — is not a cultural artifact or a mnemonic trick. It is the *optimal information-theoretic strategy* for any system built on standing waves. If creation energetics is a standing-wave framework, then the Dogon were doing information theory.
 6. **The rationality test is the unifying proof underneath everything else.** Bullets 4 and 5 describe consequences; this is the mechanism. The $\sin^2$ sensitivity matrix — the *only* physics in the model — sorts the real number line into two categories: irrational generators that produce perfect encoding (2^K distinguishable fingerprints, $\kappa < 8$) and rational generators that produce catastrophic failure (4–8 fingerprints, $\kappa \sim 10^{13}$). There is no middle ground — the gap is $10^{13}\times$ in condition number. The standing waves don't need to know number theory; they *are* number

theory. This single result explains why golden-ratio placement works in Gor'kov (§11.16), why regular grids fail in Chladni (§11.8), and why irrational-generator placement succeeds in Zeeman (§11.13). For creation energetics this means: any physical system with harmonic eigenfrequencies automatically rejects rational spatial ratios in favor of irrational ones. It's not design — it's eigenvalue structure.

And one more thing — what the kills contribute. Ten of our sixteen hypotheses were killed. That's not a failure rate; it's a *boundary map*. The kills show exactly where standing-wave physics ends and substrate-specific physics begins. Musical consonance doesn't help ($\sin^2$ orthogonality is stronger). Boltzmann statistics don't apply at classical scales ($hf \ll k_B T$). Physics-optimal force positions are information-degenerate. These are falsifiable predictions: if someone claims a standing-wave creation model, these kills tell them what it *cannot* do. That kind of boundary-setting is exactly what a rigorous creation energetics framework needs — not just “what's true” but “what's provably not true, and why.”

I don't know how much of this is useful for the conversations you're having, but I wanted to offer it. You gave us the lens that produced our best result. If any of these six findings — especially the irrationality proof, the polysemic optimality, and the rationality test — help you make the case to your peers that standing-wave organization is not speculative but mathematically necessary, then the exchange will have gone both ways. Which feels right.

One last thought

Seeing you in the West documentary honestly changed my entire outlook on life, and I can't thank you enough for it. The fact that you were attempting to explain a complex outlook on ancient symbolism for the first time, unrehearsed, and John Anthony West turned it into something that reached people — including me, years later — says something about the durability of genuine insight. It survives the medium.

That's what this project is about, really. A glass rod doesn't care whether the physicist who understands it is reading *The Theory of Sound* or *The Science of the Dogon*. The standing waves are the standing waves. Your work helped us hear them more clearly.

With gratitude and warmest birthday wishes,

Mike Tierce Independent Researcher ORCID: [0009-0004-3869-958X](https://orcid.org/0009-0004-3869-958X)

Enclosures: Paper v16 (PDF, updated March 12, 2026 — 108 pages, 39 modules, 1,473 tests), simulation repository link, experiment result summaries for S9–S13

Coherent Wave Memory

Version

© 1. The splitting formula is exact and universal.

Typeset from Markdown source using Chromium PDF rendering.

Body text in Palatino 11 pt. Mathematics rendered by KaTeX.

All quantitative claims computed from first-principles simulation code
(48 modules, 2253 automated tests) with independent FEM validation.
